**Abstract:**

**Introduction:** *Leishmania tarentolae* (*L. tarentolae*) is a nonpathogenic species of *Leishmania* genus that can be used as an expression system to produce immunogenic proteins or epitopes *in vivo* acting as an efficient and safe recombinant live vector in vaccinology. Cysteine proteases (CPs) are one group of Family C1 peptidases in *Leishmania* that are important for survival of the parasite within the host and are introduced as potential vaccine candidates. Two types of cysteine proteases, CPA and CPB, play a critical role in *Leishmania*. Previously, it has indicated that immunization with two genes or recombinant proteins of CPA and CPB individually or fused together with various adjuvant or combined with liposome are able to elicit a protective immune response against *L. major* in BALB/c mice. **Methods:** In this study, for the first time, two lines of recombinant non-pathogenic *Leishmania* were generated by transfection of a heterologous triple fusion gene encoding *cpa/cpb/egfp*. For this purpose, two different expressions approaches were taken; episomal expression using rDNA promoter, and integrative expression from rRNA locus of genome. **Results:** After genotype confirmation, the fluorescence intensity was monitored in different phases of parasite growth by both fluorescence microscopy and FACS analysis. Western blot and RT-PCR analysis showed that *cpa/cpb/egfp* tri-fused genes were specifically expressed in both lines of transgenic parasites. **Conclusion:** In this study a single fused gene was expressed in both systems and the results showed that the expression of integrated gene was higher than episomal. In addition, the present data suggest that *L. tarentolae* expressing *cpa/cpb/egfp* is a promising carrier as vectored vaccine in future research. *Vac Res*, 2014, 1 (1) : 1 - 9

**Keywords:** *Leishmania tarentolae*, Knock-in, Cysteine Protease, EGFP.

**INTRODUCTION**

Leishmaniasis is an infectious disease more prevalent in the developing countries, caused by *Leishmania* parasites and is still a serious problem in 21st century [1]. Cutaneous and visceral leishmaniasis, the two main forms of this infection, have a long history in Iran. Due to several reasons, including toxicity, long-term duration, drug resistance, side effects of current drugs, antigenic variation and complexity of the life cycle of *Leishmania*, developing an efficient approach to control the infection is challenging [2]. Importantly, leishmaniasis is known as a tool-deficient disease since no accurate system for its detection is available. Vaccination with recombinant proteins is one of the best approaches for combating or controlling leishmaniasis and early attempts at production of recombinant proteins were focused on prokaryote expression systems such as *E. coli*. However, these expression systems are not the best choices due to the limitations in codon usage, post-translational modifications, or the formation of insoluble inclusion bodies and incorrect folding of the proteins [3]. On the other hand proteins expressed in eukaryotic expression hosts are post-translationally modified and these hosts are now commonly used for protein production [4]. Since 1990, using non-pathogenic or attenuated organisms as a novel approach for protein expression has attracted attention. *L. tarentolae* is a lizard parasite and non-pathogenic for humans that can be used for development of live vaccines [5]. Promastigote form of *L. tarentolae* is able to infect macrophages in vitro [6], and is increasingly being used as a...
new eukaryotic expression system [7] and a safe and reliable live vector for mammalian vaccination [8]. CPA and CPB are members of the cysteine protease family with molecular weights of 27 and 40 kDa, encoded by cpa and cpb genes of approximately 700 and 950 bp, respectively. cpa is a single-copy gene and is highly expressed in both promastigote and amastigote phase, but cpb is a multi-copy gene and is highly expressed only in amastigotes [9-10]. Furthermore, cpb contains a short tail sequence in its C-terminal extension (CTE) that is not conserved within the family and is removed during processing and maturation [11-12] and has been shown that this region is highly immunogenic in mammalian host [12]. Interestingly, studies have shown that mutant L. mexicanaΔcpa-Δcpb parasites fail to produce lesion in mice and hamsters [13].

Discovery of reporter genes has enabled the investigators to follow the Leishmania in infected tissues or cells, to study gene function, to evaluate the effect of anti-leishmanial drugs in vitro and in vivo and monitor parasites maintenance in animals [14-15]. Among reporter genes, GFP (green fluorescent protein) is the most versatile and its expression (transiently or stably) can be detected using fluorescence microscopy or flow cytometry. There is a direct correlation between the number of a parasite and EGFP (enhanced GFP) fluorescence intensity [16]. Furthermore, studies on GFP-expressing Leishmania strains have shown that GFP could be used as a reporter gene to follow Leishmania in macrophages or tissues [17]. Although expressing proteins transitionally is faster and easier than stable expressions, it has some limitations such as variation in plasmid copy number from parasite to parasite [18]. In order to make an episomal expression vector, cells were transfected transiently with pEGFP plasmid and used to integrate the fused gene in the genome of the parasite [19]. In order to make a episomal expression vector for cpa/cpb/egfp, this triple fused gene was digested from pEGFP-cpa/cpb/egfp using BamHI and NheI and cloned into BamHI and XbaI sites of the pSP72-L-m rDNA Pro-αIR-αIR-Neo vector (kindly provided by Prof. Barbara Papadopoulou, Laval University, Canada). To evaluate in vitro expression of recombinant proteins, COS-7 cells were transfected transiently with pEGFP-cpa/cpb/egfp plasmid using the PEI (Poly sciences, Europe) reagent as described previously [20]. Briefly, the mixture of 10 mM PEI and 5 µg DNA in HBS buffer (NaCl 0.15 M and HEPES 0.02 M, pH 7.4) was added to 2.5×10^7 cells seeded in 4 well plates (SPL life sciences) at 70% confluency in serum free medium (Gibco, Germany). Six hours later, cells were washed and further incubated at 37°C humidified incubator for at least 24 h. The transfected cells harboring cpa/cpb/egfp as an episomal vector were monitored by fluorescence microscopy and fluorescent intensity at different time points was measured by flow cytometry.

**Leishmania strains and culture conditions.** Promastigotes of wild-type (WT) L. tarentolae Tar II (ATCC 30267) were cultured in vitro in M199 media (Sigma, Germany) supplemented with 5% heat-inactivated fetal calf serum (HI-FCS, Gibco, UK), 40 mM HEPES, 2 mM L-glutamine, 0.1 mM adenosine, 0.5 µg/ml hemin and 50 µg/ml gentamicin (all from Sigma, Germany) at 26°C in aerobic conditions. Promastigotes in logarithmic phase were used for transfection and in stationary-phase to determine the in vitro macrophage infectivity rate. In all experiments, an egfp-integrated L. tarentolae strain was used as positive control and maintained in complete M199 media without antibiotics [17]. Episomal-transfected parasites were cultured in complete M199 media with at least 50 µg/ml of G418. Knock-in Leishmania was maintained in the absence or presence of different concentrations of G418 (Geneticin, Gibco, UK).

**Transfection.** Parasites in the late log growth phase were harvested by two step centrifugation. First step at 700 rpm, 7 min, 4°C precipitated dead cells, second step at 3000 rpm, 10 min, 4°C pelleted the live parasites. Cells were then washed with phosphate buffered saline (PBS) and resuspended in ice-cold electroporation buffer (21 mM HEPES, 137 mM NaCl, 5 mM KCl, 0.7 mM Na2HPO4, 6 mM glucose; pH7.5) to a final density of 108 parasites/ml, as recommended [21]. Parasites (4×10^7/-300 µl) were mixed with 20 µg plasmid DNA in 0.2 cm electroporation cuvette (BioRad, USA) and kept on ice for 10 min. Electroporation was performed twice at 450 V, 500 µF using Bio Rad Pulse Electroporator (Bio-Rad, USA) and cell suspension was immediately put on ice and kept for 10 min. Electroporated parasites were then transferred to 3 ml complete M199 media supplemented with 10% FBS without antibiotic and incubated at 26°C for 24 h. To select transient transfectants, electroporated parasites were cultured in liquid M199 media containing 10 µg/ml G418 and incubated at 26°C for 48 h. Concentration of G418 in media was gradually increased during each passages, motility and viability of parasites were checked under an inverted microscope. Wild-type L. tarentolae was electroporated with no insert as control. EGFP expression in cells was monitored after each passage by an epifluorescence microscope. One of the clones which expressed both EGFP and CPA/CPB proteins was chosen for the subsequent studies.

**Genotype confirmation of transfected parasites.** Genomic DNA from parasites was isolated using GF-1 Nucleic Acid Extraction kit (Vivantis, USA) and used for DNA hybridization and PCR. For Southern blotting, the genomic DNA was digested with BamHI and separated on 0.8% agarose gel and electrotransferred to nylon membrane (Boehringer Mannheim, Germany) according to the standard protocol.
The *egfp* ORF (100 ng) was labeled with radiolabeled dCTP in PCR reaction and after purification used as a probe for hybridization. The membrane was washed three times, first with 2X SSC, 0.5% SDS at 25°C for 30 min and then 2 times with 1X SSC, 0.1% SDS at 65°C for 15 min. Positive bands were developed using a Konica Minolta developer after 5 h or overnight exposure.

Genomic DNA obtained from transfected and WT cells were amplified by PCR using primers F3001 for upstream of the 5'SSU and A1715 (Table 1) designed for the sequence covering downstream of the 5’SU and upstream of the *cpa/cpb/egfp* gene (Fig. 1).

![Western blot. Parasites in logarithmic and stationary phase were washed with PBS and solubilized directly in SDS-PAGE sample buffer and separated on 12.5% acrylamide gels [22]. Separated proteins were transferred onto nitrocellulose membranes (Schleicher & Schuell, Germany) and blocked overnight at 4°C. Blots were incubated for 2 h at room temperature with a 1:6000 dilution of horseradish peroxidase (HRP)-conjugated anti GFP monoclonal antibody (Acris antibodies GmbH) or with a 1:50 dilution of anti-CPB polyclonal antibody from vacccinated mice. HRP-conjugated goat anti-mouse IgG (Sigma, Germany) diluted 1:2500 in blocking solution was used as secondary antibody with anti-CPB. Membranes were developed using DAB as substrate.](image)

**Fig. 1.** Schematically representation of two expression cassettes. A) Cassette containing 5 SSU- *cpa/cpb/egfp-neo*-3’SSU isolated with SwaI for integration in SSU region of *L. tarentolae* genome. The positions of the promoter, restriction sites and the primers are indicated in the ribosomal locus by black arrowheads. B) Fragment carried by pSP72-L.m rDNA plasmid for episomal expression under the control of rDNA promoter. L.mr DNA: *L. major* ribosomal DNA, αIR: Intergenic region of the tubulin gene, *cpa/cpb/egfp*: fused gene. The direction of transcription is shown by the arrowheads.

**Western blot.** Parasites in logarithmic and stationary phase were washed with PBS and solubilized directly in SDS-PAGE sample buffer and separated on 12.5% acrylamide gels [22]. Separated proteins were transferred onto nitrocellulose membranes (Schleicher & Schuell, Germany) and blocked overnight at 4°C. Blots were incubated for 2 h at room temperature with a 1:6000 dilution of horseradish peroxidase (HRP)-conjugated anti GFP monoclonal antibody (Acris antibodies GmbH) or with a 1:50 dilution of anti-CPB polyclonal antibody from vaccinated mice. HRP-conjugated goat anti-mouse IgG (Sigma, Germany) diluted 1:2500 in blocking solution was used as secondary antibody with anti-CPB. Membranes were developed using DAB as substrate.

**RNA extraction and RT-PCR.** Total RNA was extracted from 107 parasites in mid-log phase using QIAGEN RNeasy plus Mini Kit (QIAGEN, Germany) according to the manufacturer’s instructions and stored at -80°C. Approximately, 2 μg of total RNA was reverse-transcribed with QIAGEN Omniscript Reverse Transcriptase Kit using oligo dT primers (QIAGEN, Germany). Transcripts of fused *cpa/cpb* were detected by amplification of the cDNA using primers H8 and CPBE (Table 1). PCR conditions were one cycle of denaturation at 95°C for 5 min followed by 30 cycles of denaturation at 94°C for 1 min, annealing at 62°C for 2 min and extension at 72°C for 3 min and a final extension at 72°C for 20 min. Any residual RNA was removed from the synthesized cDNA prior to PCR amplification by treatment of the RT product with RNase (Boehringer, Germany).

**Microscopic observation and flow cytometric analysis of parasites.** *EGFP* expression in parasites was monitored by flow cytometry and since episomal transfectant typically show plasmid copy number variation, several clones were examined. Morphology, motility and viability of transfected promastigotes in log and stationary phase were compared with the wild-type by light and Epifluorescence microscopy (Nikon, Japan). As a measure of *EGFP* expression level in transfected parasites, the fluorescence intensity of at least 105 cells gated out of all events using forward and side scatter values was quantified in GFP channel (FL-1) by flow cytometry (BD FACS Calibur) and the output data was analyzed by FlowJo software version 7.5 (Tree Star Inc., USA). All experiments were repeated at least 3 times.

**Fluorescence intensity analysis in vitro.** RAW 264.7 cells (Mouse leukaemic monocyte macrophage cell line) were cultured in RPMI medium supplemented with 10% FBS in 24-well tissue culture plates (Orange, Belgium) at a concentration of 2×105 cells per well. After 24 h incubation, media was removed and live promastigotes (transgenic and wild-type) in stationary phase were washed in PBS and added to the cells at multiplicity of infection (MOI) of 10 (ratio of parasite to cell 10:1). After 4 h, wells were washed with PBS to remove the non-phago-
cytosed parasites around the cells and incubation continued at 37°C. At different time points (24, 48 and 72 h) cells were detached by pre-warmed 0.25% Trypsin-EDTA in PBS and pelleted by centrifugation at 1700 rpm for 7 min. Pellets were resuspended in 1 ml PBS and fluorescence intensity was monitored by flow cytometry and analyzed using FlowJo software. A total of 5×10⁴ events were acquired at cell gate.

RESULTS

Plasmid DNA construct containing cpa/cpb/egfp fusion gene. Expression of the 1644 bp DNA fragment containing cpa/cpb fusion gene cloned in pCB6 vector and the ability of the hybrid protein to elicit a protective immune response against L. major has been shown previously [23]. To examine stable and transient expression of cpa/cpb gene of L. major in a homogenous live parasite system for in vitro and in vivo use, a 2.4 kb cpa/cpb/egfp fragment was introduced in L. tarentolae under the control of the regulatory sequences of rRNA Pol I promoter. For stable transfection and generation of knock-in transgenic parasites, pLEXSY-cpa/cpb/egfp construct containing 5’ SSU (~860 bps) and 3’ SSU (~1080 bps) segments homologous to 18S rRNA locus of L. tarentolae was linearized with SmaI, as previously described [19]. SSU sequences are required for integration of fragments flanked by these segments through homologous recombination (Fig. 1A). Clones with integrated cpa/cpb/egfp fused gene were selected on media containing 50 µg/ml of G418 and confirmed by PCR and Southern blot hybridization. For episomal expression, pSP72-L.m rDNA Pro-αIR-αIR-Neo vector, flanked on both sides by αIR and cloning was confirmed by PCR product of cpa/cpb/egfp fused gene with H8/GFPR (~750 bp); Lane 2: PCR product of double crossover event in rRNA locus resulted in a ~1060 bp PCR product (lane 1 of Fig. 2C). A further PCR with primers specific for 5’ SSU region complementary to genome and vector (F3001 and A1715 Fig. 1) to confirm the insertion of cpa/cpb/egfp fused gene into the rRNA locus was performed. Integration of cpa/cpb/egfp by a double crossover event in rRNA locus resulted in a ~1060 bp PCR product (lane 1 of Fig. 2C).

Genotype confirmation. Southern blot and PCR were used to confirm the presence of the introduced fusion gene in both integrative and episomal clones (Fig. 2). For Southern blot hybridization, all genomic DNA were digested with BamHI and a probe covering the egfp gene was used. Positive bands of correct size of 4 kb and 2.7 kb for integrated cpa/cpb/egfp fragment and integrated egfp alone in L. tarentolae was as positive control were observed [17] (Fig. 2A, lanes 2 and 3). In contrast, the egfp probe did not hybridize to wild-type line even after overnight exposure (Fig. 2A, Lane 1). Furthermore, the presence of the introduced gene and its correct insertion into the parasite genome were verified by PCR using primers listed in table 1 (Fig. 2B). Specific primers of egfp amplified a ~750 bp product in transfected clones and L. tarentolaeegfp+ genome as positive control (Fig. 2B, lanes 1 and 4). H8 and CPBE, primers targeting cpa/cpb sequence, produced a ~1.6 kb band (Fig. 2B, lane 2) and finally using H8 and GFPR primers resulted in a ~2.4 kb product confirming the presence of the triple fused gene in the genome of integrated parasites (Fig. 2B, lane 3). These results suggested that homologous recombination between the two homologue regions has led to the knock-in of triple fused gene sequence into a copy of the rRNA gene.

A further PCR with primers specific for 5’ SSU region complementary to genome and vector (F3001 and A1715 Fig. 1) to confirm the insertion of cpa/cpb/egfp fused gene into the rRNA locus was performed. Integration of cpa/cpb/egfp by a double crossover event in rRNA locus resulted in a ~1060 bp PCR product (lane 1 of Fig. 2C). which confirms the integration of tri-fused gene in 18S rRNA locus. Using 5’ SSU specific primers on L. tarentolaeegfp+ as positive control showed similarly sized product (Fig. 2C, lane 2). No amplification product was observed when wild-type genomic DNA was used as a template (Fig. 2C, lane 4).
Analysis of fusion gene expression in transfectants by RT-PCR and Western blot. Transcription of trifused gene at RNA level and its expression were verified using RT-PCR and Western blot, respectively. The amplification of cDNA, synthesized from total RNA of the transgenic and the wild-type parasites in logarithmic phase of growth with H8 and CPBE designed for cpa/cpb region produced a fragment of 1300bp from both episomal - and stably-transfected parasites (Fig. 3A, lanes 2 and 4). RT-PCR with cDNA of wild-type *L. tarentolae* failed to produce this product (Fig. 3A, Lane 5).

Western blot analyses on whole lysates of the integrative and episomal transfectants were performed with two different antibodies, anti-EGFP and anti-CPB. The molecular weight of tri-fused protein (CPA/CPB/EGFP) was estimated at 85kDa and immunoblot with anti-GFP antibody confirmed expression of the protein in both episomal and integrative transfected parasites (Fig. 3B). Whereas the use of this antibody for *L. tarentolae* integrated with egfp gene alone produced a ~27kDa band and the wild-type parasites did not react with anti-GFP (Fig. 3B). The chimeric protein was also detectable at both logarithmic and stationary phase of the transfected parasites using anti-CPB antibody (Fig. 3B).

Phenotypic characterization of transfected parasites by microscopy and flow cytometry. Morphological features (activity and motility) of the transgenic promastigotes were monitored daily and both *L. tarentolae* lines carrying cpa/cpb/egfp genes episomally and integrated, displayed a normal morphology (drop-like shape) of the wild-type strain with a normal length of flagellum. EGFP expression and intensity were verified and compared by Epifluorescent microscope. EGFP was fused to the CPB C-terminal and its fluorescence signal distributed in the whole cytoplasm. In spite of similarity in morphology of the transfected parasites, fluorescent intensity differed significantly between *L. tarentolae*egfp+ and *L. tarentolae* cpa/cpb/egfp+. No fluorescent signal was detected in the wild-type.

The fluorescent intensity of EGFP in the transfected parasites was measured by flow cytometry. As shown in Table 2, when CPA/CPB/EGFP is expressed stably in *L. tarentolae*, the green fluorescence intensity was stronger than the episomal form. Increasing the concentration of G418 in the medium did not increase the EGFP expression. Furthermore, the EGFP intensity in the integrated form of the recombinant parasites varied between log and stationary phases with significant decrease in stationary phase. Daily culture of the integrated form of the recombinant parasites in media containing various amounts of G418 showed that 200 µg/ml of G418 increased the fluorescent intensity (~61.44±6.12), which decreased in higher concentrations (17.96±11.26 for 500 µg/ml). Increasing the concentration of G418 to more than 500 µg/ml had no effect on EGFP intensity (data not shown).

This association between the increase in G418 and EGFP intensity was also observed in stationary phase of the parasites, cultured daily in the presence of varying amounts of G418. Expression of this gene in *L. tarentolae*egfp+ was much higher.
when expressed alone compared to the fused form, was stable (>~97%) and independent of growth phase and G418 concentration (Table 2).

**Confirmation of fusion gene expression by COS-7 Cells.** Expression of the EGFP-tagged fusion gene was also confirmed using COS-7 cells transfected with pEGFP-cpa/cpb/egfp recombinant vector or pEGFP alone by PEI 25 kDa as a transfection reagent. Comparison of EGFP fluorescent intensity in transfected cells with pEGFP-cpa/cpb/egfp vector with pEGFP bearing cells by fluorescence microscopy showed the expression of GFP in both groups, but the intensity was higher in cells transfected with pEGFP containing egfp gene alone (Fig. 4B). The flow cytometry results indicated that the level of intensity at 24 h, (35.32%) decreased to 15.79% at 48 h and 12.58% at 72 h.

### Table 2. Expression of the egfp gene in different growth phases of the parasite with different concentrations of G418 by FACS analysis.

**Fig. 4.** Fluorescence microscopy and flow cytometry results of episomal and integrative fusion gene expression in COS-7 cells

A) L. tarentolae integrated with cpa/cpb/egfp and L. tarentolae carrying an episomal gene expressing cpa/cpb/egfp grown in 200 µg/ml of G418.

B) Fluorescent microscopy of infected COS-7. a) Uninfected cells; b) cells infected with wild-type L. tarentolae; c) cells infected with L. tarentolae integrated with cpa/cpb/egfp; d) cells infected with L. tarentolae*egfp*.

C) Flow cytometry analysis of infected COS-7 cells at 48 h after infection. a) Non-infected COS-7; b) Infected COS-7 with cpa/cpb/egfp gene (pEGFP-cpa/cpb/egfp), c) Infected COS-7 with egfp gene (pEGFP).

**In vitro infection with integrated form of L. tarentolae cpa/cpb/egfp*.** The intensity of EGFP was estimated in intracellular form of the transfected Leishmania by FACS-based screening assays, fluorescence microscopy and RT-PCR in RAW 264.7 cell line. The infected cells were assessed at different time points of 24, 48 and 72 h post-infection via FACS analysis. The EGFP positive cells were representative of cell population infected with L. tarentolae integrated with cpa/cpb/egfp or egfp alone as the positive control. The percentages obtained were gated based on infected cells with recombinant L. tarentolae expressing EGFP. The best time to survey the intracellular form was 48 h post-infection, since 24 h was not enough for the parasites to differ-
entiate and after 72 h, a significant decrease in the infection rate was observed, due to the lysis of many cells caused by the infection (Table 3).

At 48 h post infection, total RNA was extracted from the infected cells with transgenic and WT parasites and were reverse transcribed to cDNA. Subsequently, PCR using H8 and CPBE primers amplified a 1300 bp fragment of cpa/cpb fused gene confirming the transcription of fused cpa/cpb genes (Fig. 5). The negative controls showed no background or DNA contamination.

### DISCUSSION

Several reports have suggested that recombinant *L. tarentolae* could be an ideal system to express proteins in native form for vaccination [24-25]. In principle, unlike classical prokaryotic systems, *Leishmania* contains all the required components for proper folding of proteins and post-translational modifications. The main advantage of this system is production of proteins in native form without the need for extra processing. One of the differences between *Leishmania* and prokaryotes is the regulation of protein expression through intergenic untranslated regions (UTRs) [26]. The potential of *L. tarentolae* in expressing heterologous proteins has been shown previously [24]. The hetero-trimeric recombinant LM-332 (Laminin) containing three α, β and γ chains has been expressed and purified successfully from *L. tarentolae* after sequential stable transfection of three different constructs. The LM protein is a high molecular weight glycoprotein, rich in cysteine residues that requires proper folding and was secreted into the media as an active protein with correct folding due to the function of endogenous chaperon proteins of the host parasite [27].

Recombinant proteins can be expressed in *Leishmania* transiently or stably and to select the best approach for expression of cpa/cpb/egfp chimeric gene, the episomal and integrative transfections were compared. Therefore, the triple fusion gene was integrated into the rRNA locus downstream of 18S ribosomal promoter [19] to be transcribed by RNA Pol I, or expressed episomally under regulation signals or regulatory elements of RNA Pol I. However, in both systems, exogenous protein was expressed from the strong rRNA promoter and transcribed by the endogenous RNA Pol I [18, 28]. The specific sequences of ribosomal rRNA promoter in plasmid vector allowed replication and its stable maintenance during inheritance as a single copy [29].

Recently, we used successfully recombinant *L. tarentolae* expressing triple fused genes including *L. donovani* A2 antigen along with cysteine proteinases (CPA and CPB without its unusual C-terminal extension (CPB-CTE)) as a live vaccine [8].

Here, we evaluated the expression potential of triple-fusion (CPA/CPB/EGFP) protein and EGFP as a reporter in

**Table 3.** Percentage of EGFP positive cells in infected RAW 264.7 cell lines with *L. tarentolae* integrated with cpa/cpb/egfp by flow cytometry at 24, 48 and 72 h post-infection
two recombinant parasite lines. Various methods were used to verify the insertion of the tri-fused gene integratively and its expression in both episomal and stably transinfected parasites, but the results pertaining to COS-7 cells infection showed that the expression of EGFP protein alone in *L. tarentolae* was higher compared to the fusion protein.

The RNA gene of *Leishmania* which is able to induce constitutive and high level expression of exogenous integrated genes are located in multiple loci and are randomly repeated in variable numbers. Therefore to increase the expression of heterologous genes in this host, the use of multiple integrations in RNA locus by repeated transfection with a linear construct has been suggested [30]. Expression of GFP as measured by Fluorescent intensity is highly dependent on various factors such as, the number of the parasites multiplied in different phases, the copy number of the integrated gene or the plasmid construct, the chaperones, as well as size, solubility, charge and folding of the fusion protein [31].

It has been shown that the higher level of metabolism in parasites during the logarithmic phase resulted in higher levels of gene expression [32]. Our data also showed that in the log phase, the intensity of EGFP was proportional to amplification of the parasites and was 2-12 times higher than the stationary phase. Expression level of EGFP alone was higher when tagged to CPA/CPB which could be due to the fact that EGFP is a small protein (27 kDa), and it is easier for the host to express it, compared to the fusion protein with a longer sequence and a higher molecular weight [33].

The fusion protein was constitutively expressed in the cytoplasm without the need for any selective pressure such as G418 which is beneficial for in vivo applications such as vaccinations; however, in case of toxic gene products, the constitutive expression of foreign genes in the host would not be possible. Compared to transient expression, stable transfection is time consuming but the disadvantage of expression by plasmid vectors is the variability in the number of the transfected parasites and the instability of the vectors in the absence of the drug pressure [34].

In conclusion, CPA/CPB/EGFP fusion protein was successfully expressed transiently in *L. tarentolae* using episomal vectors and this mode of expression is a convenient method for over expression of genes of interest in a short period of time. Furthermore, this study indicated that the *L. tarentolae* is a suitable eukaryotic host to produce eukaryotic proteins which depending on the objective of the study, both episomal and integrated approaches could successfully be applied.

**ACKNOWLEDGEMENTS**

We would like to acknowledge the help of Dr. Ali Eslamifar (Department of Clinical Research, Pasteur institute of Iran) for flow cytometry facility and Hiva Azizi (Laval University, Quebec, Canada,) for performing the Southern blot. We also thank Dr. Amir Mizbani (University Hospital Zurich, Switzerland) for English editing and S. Alizadeh (Molecular Immunology and Vaccine Research Lab, Pasteur institute of Iran) for his technical assistance.

**CONFLICT OF INTEREST**

The authors declare that they have no competing interests.
